What Determines Family Structure?

Abstract

We estimate the effects of policy and labor market variables on the fertility, union formation and dissolution, type of union (cohabiting versus married), and partner choices of the NLSY79 cohort of women. These demographic behaviors interact to determine the family structure experienced by the children of these women: living with the biological mother and the married or cohabiting biological father, a married or cohabiting step father, or no man. We find that the average wage rates available to men and women have substantial effects on family structure for children of black and Hispanic mothers, but not for whites. The tax treatment of children also affects family structure. Implementation of welfare reform and passage of unilateral divorce laws had much smaller effects on family structure for the children of this cohort of women, as did changes in welfare benefits. The estimates imply that changes in the policy and labor market variables considered here contributed to a *reduction* in the proportion of time spent living without a father by children of the NLSY79 cohort of women. This suggests that the observed increase in this non-traditional family structure in the U.S. in the last three decades was caused by other factors.

1. Introduction

The most prevalent type of family structure in which children in the U.S. are raised today is the traditional one in which both biological parents are present in the home and married. But in the past 30 to 40 years it has become increasingly common for children to experience alternative family structures, such as living with the mother with no father present, the mother and a step-father, and cohabiting parents. Children who grow up in a family with married biological parents have better education, employment, marriage, childbearing, and psychological outcomes on average than their counterparts who spend substantial parts of childhood living in alternative family structures¹. These differences are generally quite large, and dwarf the effects of income, maternal employment, and participation in welfare programs. The evidence suggests that at least part of the association between family structure and child outcomes is causal. There is much still to be learned about the consequences of growing up in alternative family structures, but there is a consensus that family structure has important consequences for children.

In contrast, there is much less known about the determinants of family structure. The proximate determinants of family structure are well-studied demographic behaviors: union formation and dissolution, transition from cohabitation to marriage, and fertility, both in and outside of unions. But the implications of adult demographic behaviors for the family structure experiences of children depend crucially on *interactions* among these behaviors. For example, the impact of being born out of wedlock is likely to depend on whether the mother and biological

¹See for example Aughinbaugh, Pierret, and Rothstein (2005), Chase-Lansdale, Cherlin, and Kiernan (1995), Gennetian (2005), Ginther and Pollak (2004), Hetherington and Stanley-Hagan (1999), Hofferth (2006), Lang and Zagorsky (2001), McLanahan and Sandefur (1994), and Sigle-Rushton, Hobcroft, and Kiernan (2005).

father subsequently marry or cohabit, and if so, how soon after the birth of the child. The impact on a child of the dissolution of a union may depend on whether the man in the union was the child's biological father or a step father, and on the duration of the union.

Economic theories of family formation and dissolution suggest a number of observable factors that affect the demographic behaviors that determine family structure.² These include the wage rates available to men and women; the tax and transfer incentives to cohabit, marry, and bear children; the legal environment governing divorce and child support provided by absent parents; and the state of the marriage market. Many studies have examined the effects of these factors on the family structure experiences of children, but most have taken a relatively narrow approach. For example, a typical study examines the impact of changes over time in one or two determinants of family structure, without considering the implications of simultaneous changes in other factors. Most studies examine only one or two of the key demographic behaviors that determine the family structure experienced by children. For example, one study might focus only on entry to cohabitation and marriage, while another study examines childbearing while single, and a third study analyzes marital dissolution.

In this paper, we propose a new approach to analyzing the determinants of family structure and its changes over time. Our approach has four distinguishing features. First, we jointly model union formation, union dissolution, and childbearing decisions. Previous analyses have integrated some of these behaviors in a single model, but none have integrated the full range of behaviors needed for a thorough analysis of family structure. A major feature of change

²See Akerlof, Katz, and Yellin (1996), Becker (1981), Neal (2004), and Willis (1999). Other theories emphasize less easily observed factors: see Ellwood and Jencks (2004).

in recent years has been de-linking of marriage and childbearing decisions. Hence it is crucial to recognize that marriage and childbearing are in fact distinct decisions, and that treating “single parenthood” as one decision rather than the consequence of related but distinct union and childbearing decisions misses key elements of changes in behavior (Ellwood and Jencks, 2004).

Second, we analyze the major hypothesized driving forces behind family structure changes jointly, including changes in public assistance policy, divorce laws, tax laws, and changes in labor market opportunities facing men and women. By considering the main driving forces jointly rather than focusing on one or two in isolation from others, as in much of the literature, we provide a more robust accounting of the factors driving family structure changes.

Third, the analysis is dynamic, and distinguishes between the short run timing effects and the long run “avoidance” effects of key driving forces. In some cases, the major changes have been in the timing of childbearing and marriage, while for others the most important aspect of change has been more radical, namely avoiding marriage or childbearing altogether (Ellwood and Jencks, 2004). Most empirical analyses do not come to grips with this issue: they are either explicitly focused on outcomes at certain ages (e.g., marriage by age 24, or non-marital childbearing by age 19), or they look at marital and childbearing transitions over short periods.

Fourth, and perhaps most important, we model the behavior of the adults who make union and childbearing decisions, but we derive from the model the consequences of these decisions for the family structure experienced by children. Thus we model choices that determine the *identity* of men who are in the mother’s household from the perspective of children: step or biological father. This approach is unique in the literature on family structure changes.

We use data from the 1979 cohort of the National Longitudinal Survey of Youth (NLSY79) to analyze the fertility, union formation, union dissolution, type of union (cohabiting versus married), and father identity (biological versus step) choices of women born from 1957 to 1964. We follow these women from the early 1970s, as they enter adolescence, through 2004, when they are in their 40s. We analyze the effects of state-year-specific policy and labor market variables over a three decade period, allowing the effects of these variables to differ for whites, blacks, and Hispanics, in recognition of the important differences in trends for these groups. We exploit both cross-state variation and within-state variation over time to identify the effects of these contextual variables, and we examine the sensitivity of the results to the source of variation. A limitation of using a narrow range of birth cohorts is that we do not have independent variation in age and calendar time. For example, welfare reform occurred in the 1990s, when the NLSY79 cohort was well past the teenage years, so our approach cannot provide a credible estimate of the impact of welfare reform on the behavior of teenagers. But the richness and long duration of the NLSY79 provide information that is not available from other sources.

The results indicate that the wage rates available to men and women have substantial effects on family structure for children of black and Hispanic mothers, but not for whites. A higher female wage rate increases the proportion of childhood spent living with no father, and reduces time spent living with the married biological father. A higher male wage rate decreases the proportion of childhood spent living with no father. For Hispanics, this is accompanied by an increase in time spent with the married biological father. For blacks there is an increase in cohabitation but not in marriage, and time spent in cohabitation increases by about the same

proportion for the biological and step fathers. Changes in tax rates also affected family structure. Implementation of welfare reform and passage of unilateral divorce laws had much smaller effects on the children of this cohort of women, as did changes in welfare benefits. However, the estimates imply that observed changes in policy and labor market factors as experienced by women in the NLSY79 cohorts actually resulted in an increase in the proportion of time their children lived with their biological fathers, or with any father. Additional simulations based on the estimates indicate that trends in wages and policy variables did not contribute much to the trend away from traditional family structure during the past 30 years.

We provide background and a brief review of previous findings in Section 2. Section 3 specifies the model and econometric approach. Section 4 describes the data. Section 5 presents the main results. Alternative specifications are discussed in section 6, and section 7 concludes.

2. Background and Previous Findings

The changes in family structure that are of interest here have been the result of a decline in marriage, increases in divorce and cohabitation, and an increase in childbearing outside of marriage. These changes are well-known and have been discussed extensively elsewhere (e.g. Bumpass and Lu, 2000; Bumpass, Sweet, and Cherlin, 1991; Cherlin, 1999; Fields and Casper, 2001; Martin et al., 2002; Stevenson and Wolfers, 2007). Here, we discuss their consequences for the family structure experiences of children, and briefly summarize previous findings on the causes of the changes.

Kreider (2008) summarizes recent family structure patterns of children using data from the Survey of Income and Program Participation (SIPP). In 2004, 58% of children under the age

of 18 were living with their married biological parents. Another 3% were living with their cohabiting biological parents. Eight percent of children were living with one biological parent and one step or adoptive parent (in 80% of these cases the biological parent was the mother). 26% were living with one parent only (in 88% of these cases, the parent was the mother). Finally, 4% were living with neither parent. For most of the 20th century up to 1970, the percentage of children living in a two-parent family remained stable at 83-85%. Between 1970 and 1990 the percentage in two parent families fell from 85 to 73% and the percentage in one parent families rose from 13 to 25%, with little further change since 1990. Family structure patterns and their changes vary substantially by race and, to a lesser extent, by ethnicity. In 2004, 67% of non-Hispanic white children lived with both biological parents, compared to 31% of non-Hispanic black children, and 61% of Hispanic children (Kreider, 2008).³

Economic theories of the determinants of union formation, union dissolution, and childbearing behavior emphasize the role of the wage rates available to men and women; the tax treatment of marriage and children; the generosity and terms of public assistance to low income families with children; and the legal environment governing divorce⁴. We briefly discuss findings from the literature on each of these factors.

³Non-Hispanic will be implicit henceforth when referring to whites and blacks.

⁴Many studies have examined the impact of abortion legalization and the availability of oral contraceptives on demographic behavior. We do not focus on these factors because both the legalization of abortion and the diffusion of easy access to oral contraceptives were completed by the early 1970s, before the women in our sample began childbearing and union formation. Other studies have analyzed the effects of marriage markets (i.e. the sex ratio) and the legal environment governing enforcement of child support obligations. We investigated these factors in an earlier version of the paper, but found them to be unimportant, so they are not considered here.

Wage rates. Becker's (1981) theory of marriage implies that the difference in potential wage rates between men and women affects the gains from specialization within marriage. The higher a woman's wage rate, the greater is the opportunity cost of staying home and raising children. The higher a potential husband's wage rate relative to the woman's wage rate, the greater is the incentive to marry in order to realize gains from specialization within marriage. A number of studies have found a negative effect of male wages and a positive effect of female wages on the prevalence of female headship. However, trends in wages do not contribute much to explaining the trend in single headship during the 1970s to 1990s.⁵ The effect of wage rates on fertility has also been studied; see Francesconi (2002) and references cited therein.

Taxes. It has been argued that expansion of the Earned Income Tax Credit (EITC) in the 1980s and 1990s caused an increase in the marriage tax penalty (Hotz and Scholz, 2003). However, there is little empirical evidence that the EITC has influenced marriage decisions.⁶

Welfare. Moffitt (1998) reviewed the large literature on the effect of welfare benefits on family behavior, and concludes that there is evidence of a positive association between welfare benefits and female headship. However, the magnitude and precision of the estimated effect are rather sensitive to specification. Furthermore, the trend in real welfare benefits in the 1980s and 1990s was downward, which should have led to a decline in female headship rather than the

⁵See, for example, Blau, Kahn, and Waldfogel (2000), Fitzgerald and Ribar (2004), Bitler et al. (2004), and Moffitt (2001). Other features of the labor market in addition to wages may affect demographic behavior as well. We investigated the effects of the unemployment rate, but dropped it from the model after finding no evidence of any effects on the behaviors of interest.

⁶See Dickert-Conlin and Houser (1998) and Ellwood (2000). There is no evidence on whether the EITC has influenced fertility. Other features of the tax code that result in marriage and childbearing subsidies have also been analyzed, with results generally suggesting small effects in the expected direction (see Alm and Whittington, 2003).

increase that was observed. Some recent studies have found more consistent evidence of a positive association between welfare benefits and female headship among disadvantaged young women, for whom welfare is likely to be a relevant option (Rosenzweig 1999; Foster and Hoffman, 2001; Hoffman and Foster, 2000). Blau, Kahn, and Waldfogel (2004) find no evidence that welfare benefits affect the likelihood that a young woman is a single mother. Light and Omori (2006) find that an increase in the welfare benefit causes a reduction in transitions into marriage and an increase in transitions to cohabitation. They also report that an increase in the welfare benefit increases divorce for black women, but not for other groups.

A recent literature examines the impact on family structure of welfare reform in the late 1980s to the mid 1990s. The majority of studies find that welfare reform caused an increase in marriage and a decrease in divorce (e.g. Acs and Nelson, 2004; Bitler et al., 2006; Gennetian and Miller, 2004). However, social experiments undertaken as part of welfare reform show no consistent impacts on union formation in the welfare population (Harknett and Gennetian, 2003), and there is some evidence that welfare reform actually caused a decrease in marriage (Bitler et al. 2004; Kaestner et al., 2003). Fitzgerald and Ribar (2004) find no significant impact of welfare reform on female headship.

Divorce laws. Many studies have analyzed the impact of enactment of unilateral divorce laws on the divorce rate and related outcomes. Peters (1986) finds no impact, but Friedberg (1998), Gruber (2004) and others do find a positive association between passage of a unilateral divorce law and the frequency of divorce. Wolfers (2006) reconciles these differences by showing that there is a positive short run impact of enactment of unilateral divorce but apparently no long run impact. This finding suggests the importance of dynamic considerations.

Alesina and Giuliano (2006) find evidence that unilateral divorce reduces out of wedlock fertility, with no impact on marital fertility. They interpret this as indicating that when it is easier to escape marriage, women who plan to have a child are more willing to have the child within marriage.

3. Model

Our goal is to understand the family structure experiences of children who reside with their biological mother.⁷ The family structures of interest are living with the biological mother and (1) the married biological father, (2) the cohabiting biological father, (3) a married step father, (4) a cohabiting step father, and (5) no man. We assume that women become at risk of entering a union and conceiving a child at age 12. A “union” refers to a co-residential romantic relationship, which may be a marriage or a cohabitation. We use a discrete time framework in which the unit of time is a month. In a given month (t), woman i 's situation is characterized by a set of fixed characteristics X_i such as her race, ethnicity, and year of birth; the outcomes of previous childbearing and union formation and dissolution decisions, Y_{it} , such as the number of children born and their ages, current marital and cohabitation status, and marital and cohabitation history; and a set of policy, labor market, and other aggregate variables Z_{ijt} , some of which may be choice-specific (j is the indicator for choices, defined below). We do not model schooling and employment decisions, and we do not condition on education and employment decisions. We

⁷The NLSY has little information on children who do not live with the biological mother. We do not distinguish living arrangements by the presence of grandparents or other non-parental adults because the model would have to be much more complex in order to do so. See Bitler et al. (2006) and DeLeire and Kalil (2002) for analyses of the presence of grandparents.

also do not model migration behavior, but we do condition on the woman's state of residence.

Each period, a woman faces a set of childbearing and union options, from which she can choose one. We assume that at most one alternative can be selected from the choice set in a given month. The set of alternatives available to a woman in a given period depends on her previous choices. For example, if she is currently married, then the option of entering a marriage or cohabitation is not available. If she is currently pregnant, then conceiving a child is not an option.⁸ We assume that if she is in a cohabitation, then the only man she can marry in the current month is her partner. We also assume that if she is currently in a union, the only man with whom she can conceive a child is her current spouse or partner. Let $A(Y_{it})$ denote the set of alternatives available to a woman in period t , given her current state Y_{it} . The alternatives are specified below. The value to a woman of choosing alternative j is specified as

$$V_{ijt}^* = \beta_{1j}X_i + \beta_{2j}Y_{it} + \beta_{3j}Z_{ijt} + \beta_{4j}X_iZ_{ijt} + \beta_{5j}\mu_i + \epsilon_{ijt}, \quad j \in A(Y_{it}) \quad (1)$$

where μ_i is a permanent unobserved woman-specific effect, β_{5j} is an alternative-specific factor loading, and ϵ_{ijt} is an *iid* shock. The inclusion of μ_i captures persistence in unobserved factors, such as preferences, characteristics of the current partner and the perceived state of the marriage market. The interaction between X_i and Z_{ijt} allows policy and labor variables effects to differ by race/ethnicity.

We do not specify an explicit theory of choice behavior, but equation (1) is consistent with choice-theoretic approaches proposed by Becker (1981) and others. It is useful to think of

⁸We consider only conceptions that lead to a live birth. Conception is treated as a choice but the birth is treated as a censoring event that ends the current pregnancy. Thus the duration of pregnancy and the decision to terminate a pregnancy are not treated as choices. Twin births are treated as an exogenous random event.

(1) as an approximation to the value function associated with a given alternative.⁹ But the parameters do not have explicit choice-theoretic interpretations, as they capture both the response to current incentives and expectations about the future evolution of the key driving forces.

If woman i chooses the alternative with the highest value in month t , and if ϵ_{ijt} follows the Type I Extreme Value Distribution, then conditional on μ the probability that she makes choice j , P_{ijt} , has the multinomial logit form:

$$P_{ijt} = \frac{\exp\{V_{ijt}\}}{\sum_{k \in A(Y_{it})} \exp\{V_{ikt}\}} \quad (2)$$

where $V_{ijt} = V_{ijt}^* - \epsilon_{ijt}$. The conditional likelihood function contribution for woman i is formed as the product, over the months for which she is observed, of probabilities for her observed choices, conditional on μ . The unconditional likelihood contribution is the integral of the conditional likelihood over the distribution of μ . The latter is treated as a discrete random factor with a two-point distribution. The model is thus a discrete-time multi-state competing risks multinomial logit model of childbearing, union formation and dissolution, and “father identity.” The model is estimated by maximum likelihood.

The full set of alternatives, not all of which are available in a given month, is

0. Do nothing
1. Conceive a child with the current man
2. Conceive a child with a new man
3. End the current union and become single

⁹Note that it is not a reduced form, as it contains variables (Y_{it}) determined by past choices.

4. Enter a cohabiting union with the current man
5. Enter a cohabiting union with a new man
6. Marry the current man
7. Marry a new man

A *new* man is defined as a man who is not the father of any of a woman's children and with whom she has never lived. The *current* man is her partner or spouse if she is currently in a union. If she is not in a union, the current man is the father of her most recent child conceived since the end of her last union, if any, or since she began conceiving children if she has never been in a union. If she is not in a union and has not given birth to any children since the end of the previous union (or ever, if she has never been in a union), then there is no current man, and alternatives 1, 3, 4, and 6 are not available. If she is currently in a union or pregnant, then as indicated above we assume that only the current man is relevant: she can conceive a child or enter a union only with the current man, so alternatives 2, 5, and 7 are not available.

Distinguishing between a new man and the current man is important because the choice between the two determines which of a woman's children will reside with, or be at risk of residing with, the biological father, and which with a step father. This important distinction has rarely been made in analyses of family *formation* behavior (see Graefe and Lichter, 1999, for an exception). We impose one key assumption in order to make it feasible to model the choice between a new man and the current man. If a woman ends a union with the current man or if she has a child with a new man, then she is not at risk of conceiving a child or entering a union again with the former current man. With this assumption, there is at most one current man.

The model is quite rich and flexible. It allows for observed and unobserved

heterogeneity, state dependence, duration dependence, and other forms of history dependence. The effects of policy and labor market conditions are allowed to vary by race and ethnicity. Geographic and time effects are included in order to allow for unobserved heterogeneity across states and over time. In practice, the specification is restricted in various ways described below, in order to avoid an excessive number of parameters. But even after imposing restrictions, the model allows substantial flexibility in the effects of contextual variables on the family structure experiences of children. These effects are derived from the model estimates, as described below.

4. Data

A. NLSY79

The NLSY79 began in 1979 with a sample of young men and women who were born between 1957 and 1964. They were interviewed annually from 1979 to 1994 and biennially since 1994. We use prospective data on female respondents through the 2004 interview, along with retrospective reports from the first interview about pre-1979 marriage and fertility behavior. We use the representative cross-section sample and supplementary over-samples of blacks and Hispanics. Here we briefly describe measurement of the key variables; more details are available in Blau and van der Klaauw (in press).

In 1979, when the sample women were between the ages of 14 and 22, the survey collected information on the beginning and ending dates (to the nearest month) of up to two marriages. In subsequent waves, information has been collected on up to three changes in marital status since the previous interview. We treat the date of separation as the date of the end of a marriage, since the issue of interest is the presence of a man in the mother's household.

However, there are many temporary separations that are followed by reuniting. Modeling the process that determines whether a couple reunites after a separation would make an already rich analysis excessively complicated. Thus, we ignore temporary separations if the duration of the separation was less than or equal to two years. Cases in which a temporary separation lasted more than two years are censored at the date of separation and no information beyond the separation date is used in the analysis.¹⁰

The survey has collected information on cohabitation in several different ways, including snapshots of cohabitations in progress at each interview date; the starting date of cohabitations that were in progress at the interview date, beginning with the 1990 interview; the starting date of cohabitations that turned into marriages that were in progress at the interview date, also beginning with the 1990 interview; and both the beginning *and* ending date of cohabitations that did not turn into marriages, beginning with the 2002 interview. Cohabitations that began and ended before the 1979 interview, or that began and ended between interviews before 1990 are missed. We combined information from the various reports to form as complete a cohabitation history as possible. The cohabitation and marriage histories were combined to form a complete union history. We performed extensive consistency checks on the union history, and examined and corrected many anomalous cases by hand (the resulting code is available on request). Cases in which exact starting or ending dates of unions are uncertain are retained, and the likelihood function is modified to account for all feasible dates. However, we dropped 401 cases with unresolvable inconsistencies in the timing of unions.

¹⁰There is one exception to this rule: if a woman never had any children prior to the end of a temporary separation that exceeded two years, her record is not censored, since there are no children affected by the separation.

The month and year of birth is reported for each child, and beginning in 1984 women were asked the month in which each pregnancy began. We use this information to identify the month of conception. If the month of conception is missing, we assume the conception occurred nine months prior to the birth. Beginning with the 1984 interview, the mother is asked whether the child's biological father is present in the household, for each of her co-resident biological children. Thus, when a woman lives with a man before or during the conception and birth, identifying fathers is straightforward. The more difficult cases are those in which a woman who has given birth to a child since the end of her previous union (or since she began bearing children, if she has never been in a union) conceives and bears another child while single. In such cases, we need to determine whether the father of the new child was the same man who fathered her previous child, but we can do this only if she subsequently enters a union (and is interviewed while the union is still in progress). If she never enters a union following the birth of a child, we cannot determine whether the father of that child was the current man or a new man. Of the 1,086 cases in which a child was conceived and born to a single woman who had given birth to a child since the end of her previous union, we are able to identify whether the father is the current man or a new man in 35% of the cases. Rather than discard the remaining cases, we modify the likelihood function to account for both of the possibilities, weighted by the probability (from equation 2) that the father was the current man or a new man.¹¹

¹¹See Blau and van der Klaauw (in press) for further details. In some cases the sequence in which events occurred is uncertain, as a result of lack of exact information on start or end dates of unions. For example, if a man moved into the mother's household between interviews and a child was born between the same interviews, we cannot always determine whether the man moved in before or after the child was born. We modified the likelihood function to account for the alternative feasible sequences in which the events occurred.

At each interview date we can determine from the household roster whether a given child is present in the mother's household. Modeling whether a child lives with the biological mother would be interesting, but is beyond the scope of this paper. The processes that determine this are thus treated as exogenous censoring processes, and the number of children present in the mother's household is adjusted when a child moves in or out. Cases in which a child is away at school or living part-time with the mother are treated as if the child is living with the mother. The death of a child is treated as a censoring event, and children's records are censored at age 18.

After dropping cases with incomplete data or unresolved inconsistencies, we are left with a sample of 4,476 women out of 4,926 eligible for inclusion.¹² Descriptive statistics on the analysis sample are displayed in Table 1, separately for whites, blacks, and Hispanics. The first panel summarizes outcomes of the demographic processes modeled here, as of the last interview. The sample women were aged about 40 on average as of the last observation.¹³ White women had given birth to an average of 1.71 children, and 21% had not given birth to any children. Black and Hispanic women had about 0.2 to 0.3 more births on average than whites. Eighty nine percent of white women had ever been married, compared to 62% of black women and 82% of Hispanic women. White women were also somewhat more likely to have ever cohabited.

The lower panel of Table 1 summarizes the incidence of the family structure outcomes

¹²The omitted cases include the 401 cases mentioned above with inconsistent marriage and cohabitation histories, and another 32 cases with problematic data on children and fathers. Another 17 cases are lost as a result of missing or inadequate data on contextual variables.

¹³Women who attrited from the sample are included in the analysis, with attrition treated as an exogenous censoring event. The last interview was in 2004 for 72% of women. Women who were interviewed in 2004 were between the ages of 39 and 47.

experienced by the 8,027 children born to the sample women as of their last interview. The children were aged 13-14 on average at the time of the last observation (after truncating at age 18; without truncating, they were 14-16). Thirty one percent of children of white mothers had ever lived without a father, compared to 76% of the children of black mothers and 45% of the children of Hispanic mothers. The proportion of childhood spent with no father also varies substantially by race and ethnicity: 12% for whites, 55% for blacks, and 22% for Hispanics. Most children of white and Hispanic mothers lived with both biological parents at some point in their childhood (94% and 85%, respectively), compared to 52% of the children of black mothers. The proportion of childhood spent living with the biological father is 80% for whites, 35% for blacks, and 68% for Hispanics. Children of black mothers were more likely to live with a stepfather and/or a cohabiting father compared to children of white and Hispanic mothers, but these differences are smaller.

B. Contextual Data

The geo-coded version of the NLSY79 provides the state of residence at each survey date, and at the time of the woman's birth and when she was age 14. We collected data from a variety of sources on welfare benefits, welfare reform, divorce laws, tax rates, and labor market conditions, and merged them with the NLSY79 data by state and year. Here we briefly describe the key measures; the Appendix provides details, and describes how state of residence was assigned for non-survey years.

The real (year 2000 dollars) Aid to Families with Dependent Children (AFDC) or Temporary Assistance for Needy Families (TANF) plus Food Stamp benefit for a family of four (single mother with three children under 18) with no other income is used as a measure of the

welfare benefit. The average welfare benefit declined in real terms over much of the sample period, with a couple of episodes of relative stability (see Figure 1A). The month and year of implementation of major welfare waivers and the TANF program for each state are used to characterize welfare reform. The welfare reform variable indicates the presence of any major change in welfare rules authorized by a waiver or TANF.¹⁴

The month and year of enactment of unilateral divorce laws were taken from Gruber (2004), which is an update of Friedberg's (1998) data. Unilateral divorce means that mutual consent for a divorce is not required. Most such laws were enacted in the 1970s, but there were occasional later cases in which states passed a unilateral divorce law (Figure 1C).

The TAXSIM program provided by the National Bureau of Economic Research (NBER) was used to compute the average tax rate for alternative filing statuses and numbers of children. The program accounts for all major features of the tax code, including the EITC and (beginning in 1977) state taxes. Rather than conditioning on the woman's observed income, we specify an arbitrary real income level that is used for all women in all years. This ensures that the only variation in the tax rate used in the model is due to tax code variation over time and across states. In the results reported here, we used the real equivalent of the year 2000 poverty line for a family of three. We estimated an alternative specification using the real equivalent of year 2000 median family income, and found similar results. The average tax rate characterizes the implications of alternative discrete marriage and childbearing choices better than the marginal tax rate. The

¹⁴TANF was implemented by all states, while not all states requested a welfare waiver. TANF incorporated many of the rule changes implemented by various states as part of their waivers, including time limits and welfare-to-work (workfare, learnfare) programs. TANF was implemented by states between 1996 and 1998. See Figure 1B for the aggregate timing pattern.

average tax rate is treated as a choice-specific variable that depends on the marital status and number of children associated with each alternative a woman faces. Marital status and number of children are outcomes of the choice processes and therefore endogenous if there is serially correlated unobserved heterogeneity. Conditioning on the permanent woman-specific effect (μ_i) and integrating it out of the likelihood function accounts for this source of endogeneity if the heterogeneity is permanent. Thus, in our analysis, the tax rate varies over time, across states, and by fertility and marital status. There was rapid growth in the tax subsidy to children for low-income women beginning in the 1980s (see Figure 1D). Much of this growth is a result of large expansions of the EITC, which provides benefits almost exclusively to low-income families with children (and is refundable, hence the possibility of a negative average tax rate).

The female wage rate is measured by the mean real full time average hourly earnings of women aged 16-47. The state-year-specific mean wage rate is constructed separately for whites, blacks, and Hispanics using data from the Current Population Survey (CPS) by dividing weekly earnings in the survey week by hours of work per week. The age group 16-47 spans the (employment-eligible) age range of the NLSY sample in the years for which we have data. In order to avoid introducing composition effects into the wage trends, we regression-adjust wages for education and age. The wage measures used here are standardized to a constant level of education (high school graduate) and age (26-30). The male wage rate is constructed in the same way, for a sample of men aged 18-49. Note that the wage rate is *not* choice-specific: it is not conditioned on marital status or fertility. It is also not conditioned on the education or other human capital characteristics of the women in our sample. Figures 1E-1G show that the male-female wage gap narrowed for all three groups through the mid 1990s, especially for Hispanics,

but has been relatively constant more recently. In absolute terms, mean real wages are higher in 2004 than in the 1970s only for white and Hispanic women.

5. Results

The parameter estimates and standard errors on the policy and labor market variables are reported in the Appendix (Table A-1).¹⁵ The parameter estimates are not particularly informative, so we do not discuss them. The specification reported here includes the six contextual variables described above, each interacted with indicators for black and Hispanic, thus allowing the effects to differ freely by race/ethnicity. The specification also includes dummies for nine census regions and the 22 largest states, a quadratic in calendar time, dummies for five (or in some cases ten) year periods, and dummies for several individual years in the mid 1990s, around the time of welfare reform. The model is nonlinear and has a large number of parameters. Given the relatively small numbers of women from the less-populated states, as well as the low frequency with which some alternatives were chosen in some of the calendar years, it was not feasible to incorporate full sets of state fixed effects and calendar year fixed effects, leading us to group some of them together instead. The geographic and time controls are included in order to avoid

¹⁵In addition to the contextual variables, the specification includes black and Hispanic indicators, a quadratic in the woman's age, the number of children fathered by the current man, the cumulative number of cohabitations, whether a single woman was in a cohabitation or a marriage in her previous spell, quadratics in the ages of her youngest and oldest children, and quadratics in the duration of the current cohabitation and single spells. See the Appendix (Table A-2) for the estimates on these variables. In the interests of empirical tractability we imposed a substantial number of exclusion restrictions in cases in which a given variable consistently had small and statistically insignificant effects. In alternative specifications, we found that the mother's date of birth, number of marriages, total number of children, duration of marriage, and duration of pregnancy could be excluded with little impact on the predictions of the model.

attributing the effects of unobserved differences across states and over time to the contextual variables of interest. However, the geographic controls also absorb the true effects of permanent cross-state differences in the contextual variables, as well other permanent differences across states, thus leaving only variation over time around state-specific averages to identify the effects of the contextual variables (Keane and Wolpin, 2002). Below, we discuss the sensitivity of the results to specifications with alternative sets of geographic controls.

We use the parameter estimates to simulate the life history of each woman in the sample. The simulations condition only on the woman's race/ethnicity, age, and the state of residence in each year in which she is observed, which determines the values of the contextual variables and the time and geographic controls. A woman is assigned a heterogeneity type (a value of μ) based on a draw from the estimated heterogeneity distribution. Each woman starts out single and with no children at age 12. The estimates are used to compute the probability of each of the three events in the choice set in this case (enter a cohabitation, enter a marriage, conceive a child), given her type (μ), race/ethnicity, and state of residence at age 12. A random number generator determines which, if any, event occurs. If the event is conceiving a child, a pregnancy duration is randomly assigned according to the observed distribution of pregnancy durations in the sample. The Y_{it} variables are updated according to which event, if any, occurred, and the process is repeated for the next month. If pregnant, the birth occurs at the assigned duration. The process continues through the last month in which the woman is observed.¹⁶ This procedure is repeated

¹⁶The simulated data for children are truncated at age 18. As in the data, some children are not observed for their entire childhood in the simulations, because they have not reached age 18 in the last period in which the mother is observed. In the simulations, there are no deaths, no twin births, and no cases in which children move in or out of the mother's household.

100 times for each woman in order to average out random fluctuations. To generate standard errors for the simulations, we took 200 random draws from the joint distribution of the parameter estimates, and repeated the entire simulation procedure for each draw. We report the mean and standard deviation of the resulting simulations.¹⁷

To illustrate the effects of wage rates and the welfare benefit, we compare two scenarios (separately for each variable): one in which the variable is held constant for all women and all periods at its overall sample mean, and another in which it is held constant at the mean plus one standard deviation. For the tax rate we compare one scenario in which the tax rate for each combination of marital status and number of children is held constant at its sample mean to three alternative counterfactuals: one in which the tax gain from marriage is eliminated; a second in which the tax gain from having children conditional on marriage is eliminated; and a third in which the tax gain from having children conditional on being unmarried is eliminated. For welfare reform and unilateral divorce, the two scenarios hold the variable constant at zero and at one. The values of the contextual variables used in the simulations are shown in Table 2.

Table 3 shows simulated effects of the contextual variables on the proportion of childhood spent in the five family structures of interest. The results show that an increase in the female wage rate causes an increase in the proportion of childhood living with no father. The effect is very small for children of white mothers, but is large for children of black and Hispanic mothers. The implied wage elasticities of the proportion of childhood spent with no father are

¹⁷In the baseline simulation the contextual variables take on their observed values. The Appendix (Table A-3) compares simulation results for selected variables characterizing choice behavior to the observed values in the data. The model reproduces most aspects of the data reasonably well, but under predicts the proportion of childhood living without any man present.

1.36 for children of black mothers and 3.64 for children of Hispanic mothers.¹⁸ The positive effect is consistent with the idea that the gain from being in a union is decreasing in the female wage, conditional on the male wage. However, it is interesting to note that time spent with a married step father increases for blacks. Most of the increase in the proportion of childhood spent living with no man comes at the expense of time spent with the married biological father.

The effects of an increase in the male wage rate are almost all opposite in sign to the effects of an increase in the female wage rate. This is consistent with the prediction of Becker's model of specialization in marriage. The simulated effects are small for children of white and black mothers. For children of Hispanic mothers there is a decline in time spent with no father and with a married step father, accompanied by an increase in time spent living with the married biological father. The decline of .037 in the proportion of childhood spent with no father is quite large relative to the baseline of .122 for children of Hispanic mothers.

An increase in the welfare benefit is estimated to cause a decrease in the proportion of childhood spent living with the married biological father for all three groups, but the estimates are not significantly different from zero. The negative effect is consistent with the predictions of economic models of the family (e.g. Neal, 2004; Willis 1999). The decrease is accompanied by an increase in time spent living with no man (except for blacks) and cohabiting men, but the proportion of childhood spent living with a married step father also increases.

The simulated effects of the tax gains to marriage are quite small and precisely estimated,

¹⁸From Table 2, a one standard deviation change in the wage rate is a 13.4% increase. The baseline simulated proportion of childhood spent living with no father is .33 for blacks and .12 for Hispanics (see Appendix Table A-3). The simulated change of .060 for blacks in Table 3 is an 18.2% increase over the baseline value, yielding an elasticity of $1.36 = 18.2/13.4$. For Hispanics, the corresponding elasticity estimate is $3.64 = 47.5/13.4$.

in the sense that we can reject large effects with considerable confidence. The simulated effects of the tax gain from having children conditional on being married are also quite small in most cases, but a few of the effects are a bit larger. It is surprising that the tax gain from children conditional on marriage is estimated to *decrease* the proportion of childhood spent living with a married father by about .025 for all three groups, with most of the decrease accounted for by an increase in time spent living with no father. This is a puzzling finding, and is robust across the alternative specifications we have estimated. The simulated effects of the tax gain from children conditional on being unmarried are also counterintuitive, resulting in an increase time spent with the married biological father and a decline in time spent with no father present.¹⁹

The last two panels in Table 3 show the simulated effects of welfare reform and unilateral divorce. The simulations show some moderately large effects in a few cases, but none are significantly different from zero. Welfare reform is estimated to cause an increase of .049 in the proportion of childhood living with the married biological father for children of black mothers. Unilateral divorce also causes a rather large increase in the proportion of childhood living with the married biological father for children of black and Hispanic mothers. The lack of precision of these estimates is most likely due to the fact that most of the changes in unilateral divorce laws were in the early 1970s (see Figure 1C), so these changes affected relatively few individuals in our sample during the prime childbearing years. Welfare reform occurred in a fairly narrow time span from the late 1980s through 1997 when the NLSY79 cohort was in their 30s, past prime

¹⁹Further examination of these effects would require an analysis of income and substitution effects (both within and across periods) of the tax gain on labor supply and earnings. Note that in a household bargaining model with divorce and child support transfers, the impact of an EITC-type tax credit, which is especially beneficial to single mothers, on divorce has an ambiguous sign (Francesconi et al, 2007).

childbearing ages.

Family structure changes are thought to have different effects on children in different stages of childhood (e.g. Hill et al., 2001; Moore et al. 2001). We examined whether the effects shown in Table 3 were concentrated in particular phases of childhood: early (0-4), middle (5-11), and late (12-17). These are hypothesized by developmental psychologists to be distinct stages in the developmental life course. The results (not shown) do not indicate any systematic tendency for the effects to be concentrated in particular stages of childhood. In a few cases, the effects are stronger at younger ages (e.g. welfare reform for blacks), while in a few other cases the effects are stronger at older ages (e.g. tax gain to having children for whites). In the great majority of cases the effects are quite similar across the age groups.

The outcomes shown in Table 3 are measures of the “stock” of time spent in alternative family structures. It is of considerable interest to investigate the underlying determinants of these stocks, which include both a child’s family structure at birth, and “flows” of men in and out of a child’s household. Consider the effect of a one standard deviation increase in the female wage rate, which was estimated to cause an increase in the proportion of childhood living with no father of .060 for children of black mothers, and .057 for children of Hispanic mothers. The probability that the mother was single at the birth of the child increases by .038 (se .035) for blacks and .056 (se .031) for Hispanics as a result of the higher female wage, accounting for a substantial part of the increase in the proportion of childhood living with no father. Figure 2 shows the simulated effects of the wage increase on annual transition rates of children of black mothers among the various family structures, along with 95% confidence bands. The annual transition rates out of marriage increase by .02 to .03, thus contributing to the increase in time

spent with no father. Cohabitations break up at a more rapid rate as well. Surprisingly, transitions into cohabitation and marriage also increase. The corresponding effects for children of Hispanic mothers (not shown) are all in the same direction, but smaller and less often significantly different from zero.

Another interesting finding in Table 3 is the negative effect of a higher male wage rate for children of Hispanic mothers on the proportion of childhood living with no father (-.037), and the corresponding increase in time spent living with the married biological father (.059). The simulated effect of an increase in the male wage rate on the probability that the mother was single at the birth of the child is -.046 (se .023) for children of Hispanic mothers, which can account for all of the -.037 change in the proportion of childhood spent with no father. Changes in transition rates contribute little in this case (not shown).

We now use the estimates to address a different question: how did the observed trends in the contextual variables affect family structure, compared to a counterfactual scenario in which the contextual variables remained constant at their state-and-race/ethnicity-specific 1970-1974 means, the values that prevailed when the NLSY79 cohort of women was entering adolescence. The first panel of Table 4 shows the simulated impact of exposure to the observed values of the contextual variables compared to the counterfactual in which they all remained at their early 1970s levels. For children of white mothers, the observed changes in the contextual variables caused an increase in the proportion of childhood spent with the married biological father of 6.1 percentage points, and decreases of 2.3 percentage points in time with a married step father, and 3.2 percentage points in time spent with no father. These are moderately large effects, given the simulated baseline proportions of 87% with a married biological father, 5% with a married step

father, and 7% with no father (see Appendix Table A-3). The simulated effects for the children of black mothers are similar in sign and magnitude, but are not as precisely estimated. The effects for Hispanics are substantially smaller. The results imply that if anything, the changes in the contextual variables during the past 30 years actually helped reduce the proportion of time children lived without their biological father (or without any father) for this cohort, during a period in which this proportion rose overall.

The remaining panels of Table 4 show the effects of changing one variable at a time. An important source of the total effects for whites and blacks is the change in the average tax rate, which declined substantially for families with children beginning in the mid 1980s. This was reinforced by a declining female wage rate for blacks. For whites, the decline in the welfare benefit also contributed to the observed changes. For Hispanics, female and male wage trends that both caused less time spent in marriage and with the biological father were offset by the effects of trends in tax rates and welfare benefits. The effects of welfare reform and unilateral divorce are negligible for all three groups, not surprising given the small estimates in Table 3.

The final issue considered here is whether the model can explain the large changes in family structure in recent decades in the U.S. There are no consistent time series available from the 1970s onward on children living in cohabiting arrangements and on biological versus step fathers, so the only trend in family structure we can analyze is for the proportion of children living with the mother only. We compare results from two counterfactual simulations in order to determine how much of the observed trend in the proportion of children living with no father from the early 1970s through the early 2000s can be explained by our model: in one case we hold all the contextual variables constant at their 1970-1974 state-race/ethnicity-specific means,

and in the other case we hold them all constant at the corresponding 2000-2004 values.

Comparing the two simulations gives an estimate of the effect of the observed changes in contextual variables on the proportion of childhood spent living with no father.

Table 5 uses CPS data to show that the proportion of children living with no father increased from .095 to .191 for whites from 1970-74 to 2000-04, and from .388 to .572 for blacks. For Hispanics, the time series begins in 1980, and there was a small increase from .253 to .278 from 1980-84 to 2000-04. The table shows that our simulations cannot explain any of the observed change for whites, and only a very small proportion for blacks. The simulations over-predict the magnitude of the increase for Hispanics, but it is not clear how much weight to put on this, given that the composition of the Hispanic population is changing over time, while the NLSY79 Hispanic sample is representative only as of 1979. One other series available on a consistent basis is the fraction of those children living with no father whose mother has never been married. Table 5 shows that this increased from .086 to .417 since the early 1970s, a change of .331. The observed changes in the contextual variables predict an increase of .037, or only about one tenth of the observed change. Thus, as in much previous research, our estimates indicate that the economic and policy variables we considered contributed little to the observed changes in family structure.

6. Alternative specifications

The results discussed above are based on a specification with a rich set of controls for fixed geographic effects: 22 state dummies and nine census division dummies. As discussed above, this specification has the advantage of controlling for unobserved differences across

states and census divisions that could be correlated with the contextual variables. The source of identification is variation in state-specific trends in the contextual variables around the state-specific means. In order to determine whether the results are sensitive to the source of identification, we re-estimated the model with two alternative specifications: one that drops the state fixed effects, and one that drops the nine division dummies as well. Table 6 shows the simulated effects of the contextual variables on the proportion of childhood spent living with no father, for alternative model specifications. Column 1 reproduces the results for the main specification, from the last column of Table 3.²⁰ Columns 2 and 3 report results from the new specifications. Most of the simulated effects are very similar, suggesting that responses to permanent differences across states are similar to responses to variation around means within states. There are a few notable differences, however: the effect of the female wage rate for blacks declines from .100 to .074; the effect of the male wage rate for Hispanics changes from -.045 to -.062; the effect of the welfare benefit for blacks changes from -.005 to .031; the effect of welfare reform for blacks changes from -.022 to -.001; and the effect of unilateral divorce changes from -.049 to .009 for blacks and from -.061 to -.026 for Hispanics.

Another important feature of the specification is the absence of controls for the characteristics of women, other than race/ethnicity. The effects that we attribute to the contextual variables could be due in part to differences in characteristics of women not included in the specification. To investigate this possibility we re-estimated the model with three alternative specifications, adding controls for the woman's own family structure at age 14, her completed

²⁰The entries in column 1 of Table 6 differ slightly from the corresponding entries in Table 3 because the results in Table 6 use the actual point estimates of the parameters rather than 200 draws from the parameter distribution as in Table 3.

years of schooling, and her cognitive achievement, as measured by the Armed Forces Qualification Test (AFQT) score.²¹ Columns 4-6 in Table 6 show the results for these specifications. Controlling for the woman's family structure at age 14 has very little impact on the simulated effects (compare columns 1 and 4). Adding completed years of schooling has relatively little impact as well (compare columns 4 and 5), with a couple of exceptions. But adding the AFQT score in column 6 changes the results substantially, yielding much smaller effects of several of the contextual variables. This is somewhat surprising, but it turns out that the AFQT score is positively correlated with all of the contextual variables, with a correlation as high as .27 with the male wage rate. And the correlation between education and both the male wage and the average tax rate is .10. This is presumably due to cross-state correlations between AFQT, education, and state-specific time variation in the contextual variables. Thus the effects that we attribute to the contextual variables may be due in part to education and cognitive ability. However, both education and cognitive ability are malleable, and the contextual variables may affect family structure in part via effects on education and cognitive ability of mothers. This is an interesting possibility to examine in future research.

7. Conclusions

The evidence presented here suggests that the family structure experiences of the children of women born from 1957 to 1964 have been influenced by trends in male and female wage rates and tax rates. Trends in welfare benefits, welfare reform, and unilateral divorce had relatively

²¹Education and AFQT are treated as exogenous, and we do not attach any specific interpretation to their effects.

little impact on the family structure experiences of these children. The results show that both the magnitudes of the effects and the channels through which they operate are often quite different for whites, blacks, and Hispanics. The methods used to produce this evidence are rather new, and the consistency between our findings and those of previous studies, for the outcomes that can be compared, is encouraging. But we readily acknowledge several limitations that suggest caution in drawing any strong conclusions based on the results.

First, our results apply only to a narrow range of birth cohorts, and it is difficult to see how to generalize them in the absence of comparable data for other cohorts. Second, a limitation of the NLSY79 data is that we have little information on children who do not live with the biological mother. Thus while our model is rich, it omits this potentially important channel through which the contextual variables could affect family structure. Third, we ignore several other processes that may be important for child outcomes, including those that affect the presence in the household of step siblings and grandparents. Temporary separations are ignored as well. And a potentially important channel through which several of the contextual variables may operate is the labor market, suggesting the need to model employment choices. All of these channels are worth exploring in future work.

An important motivation for our analysis was the challenge posed by Ellwood and Jencks (2004) to develop new approaches to analyzing the determinants of family structure change. We believe that our analysis has been successful in responding to several of their suggestions for new directions in this field. But the results of our analysis imply that trends in the contextual variables considered here cannot account for the trend away from traditional family structure in the last 30 years. Explaining this trend remains an important challenge. Another challenge that we are pursuing in ongoing research is to develop a theoretical model that can provide an explanation and interpretation of the main results, including the large differences across racial and ethnic groups.

Appendix

Wage rates. The mean hourly wage rate was computed for men and women aged 16-47 by year, state, and race/ethnicity from the Merged Outgoing Rotation Group (MORG) files of the Current Population Survey (CPS) for 1979-2004, and from the May CPS files for 1970-1978. The wage rate is computed by dividing weekly earnings by hours of work per week. Cases were included in the computation only if weekly earnings were at least \$150 (in year 2000 dollars), hours of work were at least 30, and the resulting hourly wage rate was between \$2.00 and \$200.00. Weekly wages were topcoded at \$999 from 1970-1988, \$1,923 from 1989-1997, and \$2,884 from 1998 on. Wages were deflated using the Personal Consumption Expenditure Deflator (PCED, base year 2000), and weighted by the sampling weight provided in the CPS files. Before 1977, some states are not separately identified, so for those years the mean wage for the group of states (by sex, year, and race/ethnicity) is assigned to each state in the group.

Weekly earnings are given in categorical form before 1973 in the May CPS files. The midpoint of each category is used in this case, with \$600 assigned for the highest category in 1972 (when the lower limit is \$500), and \$300 assigned in 1970-1971 (when the lower limit of the highest category is \$200). In the 1973-1978 May CPS files, the continuous weekly earnings variable is missing for some cases, but the categorical version of earnings is also on the file for those years. If the categorical variable is not missing, it is used to compute the wage when the continuous measure is missing (the categories are the same in 1973-1978 as in 1972). Hispanic ethnicity is not identified in the May CPS in 1970-1972. The real 1973 means by state were used for 1970-72 for Hispanics.

The wage rate is regressed on education dummies (four groups), age dummies (six

groups), and state of residence, separately by year, sex, and race/ethnicity. A wage rate is predicted for each employed individual, holding education constant at high school graduate and age constant at 26-30. Wages are then averaged within state-year-sex-race/ethnicity cells. In order to smooth out spurious fluctuations due to small sample size in some cells, we use a three year moving average of wage rates, within state-sex-race/ethnicity groups. Cells with fewer than 30 cases (after averaging) are omitted. This resulted in the loss of 5.4% of the potential NLSY person-month observations, with the loss disproportionately larger for blacks and Hispanics.

Welfare Benefit. Data for the AFDC/TANF cash benefit for a family of four with no income are from Robert Moffitt's welfare benefits file for the years 1970-1998 (<http://www.econ.jhu.edu/People/Moffitt/datasets.html>). Data for 1999-2004 are from the 2004 Green Book (<http://www.gpoaccess.gov/wmprints/green/index.html>), the Congressional Research Service (2005), and the Urban Institute's Assessing the New Federalism web site (<http://www.urban.org/center/anf/index.cfm>). In some recent years data are only available for a family of three. The benefit for a family of four was estimated by applying the state-specific ratio of benefits for households of size three and four, which are both available for 1996-1998 and 2003-2004. The Food Stamp guarantee for a family of four is from Moffitt's data base for 1970-1998, updated with data from the web site of the Food and Nutrition Service.

Welfare Reform. The timing of implementation of welfare waivers and TANF are from the web site of the Office of the Assistant Secretary for Planning and Evaluation, Department of Health and Human Services.

Divorce Law. The year of enactment of unilateral divorce is from Gruber (2004), Table 1.

Tax Rates. Tax rates are computed using the NBER's TAXSIM program. Tax rates were

computed for two income levels: the poverty line for a family of three (one adult and two related children) in 2000 (\$13,874), and for median family income in 2000 (\$50,372), both adjusted for inflation in other years. All income was assumed to be from earnings. Child care expenditure for a poor family was assumed to be 23% of income, and for a median-income family 6% of income (Johnson, 2005). All children were assumed to be under 17 for purposes of the child tax credit. Taxes were computed for alternative numbers of children (0-9) and filing statuses (single, head of household, and married filing jointly). State taxes are included from 1977-2004, but are not included for 1970-1976. In married families, 60% of earnings were allocated to the husband and 40% to the wife.

Assigning state of residence before the first survey and between survey years.

Respondents were asked to report their state of residence at age 14 and at birth, but the dates of moves are not recorded. We assign state of residence for years before the first survey year (1979) based on which reporting year (year of birth, year in which the respondent turned age 14, and 1979) is closest in time to a given calendar year. The state of residence is reported in each interview from 1979-1994. The state reported is assumed to apply for the entire calendar year. In 1996 and 1998, state of residence is ascertained at the survey date, but the dates of moves are not recorded. We assign the 1995 and 1997 state of residence according to which interview month in the adjacent survey year is closest in time to 1995 or 1997. In 2000, 2002, and 2004, the dates of moves between interviews were recorded, so we assign state of residence for the between-survey years according to where the respondent lived longest during the between-survey years. The survey-date state of residence is assigned to the entire calendar year for that survey year.

Table 1: Descriptive Statistics on Women and Children as of the Last Interview

	White	Black	Hispanic
Demographic outcomes of women			
Number of children born	1.71	1.89	1.99
No children born	0.21	0.18	0.17
Ever married	0.89	0.62	0.82
Ever cohabited	0.43	0.36	0.39
Age at last observation	40.5	39.9	39.6
Number of women	2,292	1,338	846
Family structure outcomes of children			
Ever lived with no father	0.31	0.76	0.45
Proportion of childhood lived with no father	0.12	0.55	0.22
Ever lived with married father	0.95	0.61	0.87
Ever lived with married biological father	0.92	0.47	0.79
Ever lived with married step father	0.14	0.20	0.17
Ever lived with cohabiting father	0.14	0.27	0.23
Ever lived with biological cohabiting father	0.04	0.10	0.09
Ever lived with step cohabiting father	0.11	0.18	0.16
Ever lived with biological father	0.94	0.52	0.85
Proportion of childhood lived with biological father	0.80	0.35	0.68
Ever lived with stepfather	0.18	0.28	0.24
Age of child at last observation	12.9	14.0	13.3
Number of children	3,864	2,496	1,667

Notes: The last interview was in 2004 for 72% of women. The child outcomes are censored at age 18. Observations are weighted by the inverse of the number of event histories per woman. As described in the text, a woman may have multiple event histories if there is ambiguity about the timing or sequence in which demographic events occurred. In these cases, an event history is generated for each of the feasible timing or sequencing alternatives. See the text for further discussion.

Table 2: Summary Statistics on Contextual Variables

A. Means and standard deviations		
	Mean	SD
Monthly welfare benefit for a family of four with no income	1013	265
Unilateral divorce law in effect	.552	
Welfare reform in effect	.210	
Male hourly wage rate	12.12	1.80
Female hourly wage rate	9.70	1.30

B. Mean tax rate by marital status and number of children										
Number of children:	0	1	2	3	4	5	6	7	8	9
Married	.170	.061	.030	.028	.027	.027	.026	.026	.025	.025
Single	.228	.077	.035	.031	.030	.028	.028	.027	.027	.026

Note: Unit of observation is a state-year-race/ethnicity cell. Observations are weighted by the cell sample size in the NLSY sample. Dollar amounts are in year 2000 dollars, using the Personal Consumption Expenditure Deflator. The simulations reported in Table 3 use the means reported here as the baseline. The welfare benefit and wage counterfactual simulations add one standard deviation to the mean. The counterfactual for the “eliminate the gain to marriage” simulation replaces the tax rates for singles with the tax rates for married couples. The counterfactual for the “eliminate the gain to having children if married” simulation replaces the tax rates for married couples with children with the tax rate for married couples without children (.170). The counterfactual for the “eliminate the gain to having children if single” simulation replaces the tax rates for single women with children with the tax rate for single women without children (.228). The unilateral divorce and welfare reform simulations compare values of zero to one.

Table 3: Simulated Effects of Changes in Contextual Variables on the Proportion of Childhood Spent in Alternative Family Structures

	Change in proportion of childhood lived with the biological mother and:				
	Married biological father	Cohabiting biological father	Married step father	Cohabiting Step father	No father
Female wage rate					
White	.001 (.016)	-.001 (.002)	-.002 (.006)	-.001 (.001)	.002 (.009)
Black	-.049 (.032)	-.005 (.003)	-.003 (.008)	-.003 (.003)	.060 (.030)
Hispanic	-.077 (.043)	-.002 (.003)	.020 (.010)	.001 (.004)	.057 (.033)
Male wage rate					
White	-.019 (.018)	.001 (.002)	.008 (.007)	.002 (.002)	.008 (.010)
Black	-.011 (.035)	.017 (.012)	-.003 (.012)	.011 (.008)	-.014 (.028)
Hispanic	.059 (.025)	-.002 (.003)	-.016 (.009)	-.003 (.003)	-.037 (.014)
Welfare Benefit					
White	-.021 (.015)	.000 (.001)	.010 (.006)	.002 (.002)	.009 (.009)
Black	-.004 (.038)	.002 (.004)	.007 (.012)	.002 (.004)	-.008 (.032)
Hispanic	-.037 (.025)	.002 (.003)	.016 (.008)	.005 (.004)	.014 (.016)
Tax gain from marriage					
White	-.001 (.002)	.000 (.001)	.001 (.001)	.000 (.001)	.000 (.001)
Black	-.009 (.006)	.000 (.001)	.003 (.002)	.000 (.001)	.006 (.004)
Hispanic	-.007 (.006)	.001 (.001)	.002 (.002)	.000 (.001)	.004 (.003)
Tax gain from a child if married					
White	-.025 (.008)	-.000 (.001)	.007 (.003)	.001 (.001)	.017 (.005)
Black	-.025 (.026)	.002 (.002)	-.003 (.011)	.003 (.003)	.022 (.024)
Hispanic	-.026 (.021)	.001 (.003)	.001 (.007)	.002 (.003)	.021 (.013)
Tax gain from a child if single					
White	.058 (.020)	.000 (.001)	-.017 (.007)	-.002 (.002)	-.038 (.013)
Black	.011 (.036)	-.005 (.005)	.013 (.015)	-.005 (.006)	-.014 (.032)
Hispanic	.041 (.039)	-.003 (.005)	-.001 (.010)	-.005 (.006)	-.032 (.026)
Welfare reform					
White	-.003 (.020)	-.001 (.002)	.004 (.010)	-.001 (.002)	.001 (.011)
Black	.049 (.060)	-.001 (.005)	-.021 (.019)	-.004 (.004)	-.023 (.046)
Hispanic	.008 (.037)	-.002 (.004)	.010 (.014)	-.001 (.004)	-.013 (.021)
Unilateral divorce					
White	-.004 (.030)	-.001 (.004)	.002 (.011)	.000 (.003)	.004 (.017)
Black	.066 (.068)	-.002 (.007)	-.010 (.021)	-.005 (.007)	-.049 (.054)
Hispanic	.102 (.065)	-.007 (.009)	-.022 (.018)	-.009 (.009)	-.064 (.044)

Notes: The five family structures are mutually exclusive and exhaustive, so the entries in each row sum to one. Standard errors are in parentheses, computed as described in the text. Entries in bold are significantly different from zero at the 10% level. The wage rate and welfare benefit simulations show the effect of a one standard deviation increase, relative to the mean. The tax gain simulations show the effect of the observed mean tax rates relative to the counterfactual of the tax rate for singles set equal to the tax rate for married households (tax gain from marriage), the tax rate for married families with children set equal to the tax rate for married families with no children (tax gain from a child if married), and the tax rate for single mothers with children set equal to the tax rate for single mothers with no children (tax gain from a child if single). The welfare reform and unilateral divorce simulations show the effect of setting the variable equal to one, relative to setting it equal to zero. See Table 2 for the data values used in the simulations. Childhood is defined as birth up to but not including age 18.

Table 4: Simulated Effects of Observed Changes in Contextual Variables

	Proportion of Childhood lived with the biological mother and:				
	Married biological father	Cohabiting biological father	Married step father	Cohabiting Step father	No father
All

Black	.007 (.007)	-.000 (.001)	-.001 (.002)	-.001 (.001)	-.004 (.007)
Hispanic	.008 (.006)	-.001 (.001)	-.002 (.002)	-.001 (.001)	-.005 (.004)

Notes: The five family structures are mutually exclusive and exhaustive, so the entries in each row sum to one. Standard errors are in parentheses, computed as described in the text. Entries in bold are significantly different from zero at the 10% level. The simulations compare the baseline, in which all contextual variables take on their observed values, to a counterfactual in which a given contextual variable is held constant at its state-specific 1970-1974 mean value. For the tax rate, the 1977-1981 means are used, because state taxes were not included in the 1970-1974 data. In all cases, the state fixed effects, division fixed effects, time trends, and period effects take on their actual values.

Table 5: Comparison of Actual and Simulated Trends in Living Arrangements of Children

	Actual Trend			Simulation
	2000-04	1970-74	Difference	
Children living with mother only, as a proportion of children living with mother only and two-parent families				
White	.191	.095	.096	-.028
Black	.572	.388	.184	.013
Hispanic	.278	.253	.025	.036
Children living with mother only: proportion of mothers never married	.417	.086	.331	.037

Source: Actual trends: <http://www.census.gov/population/www/docdemo/hh-fam.html#ht>, Tables CH1-CH5.

Notes: For Hispanics, the data series begins in 1980, so the simulation uses 1980-84 instead of 1970-74.

Table 6: Simulated Effects of Contextual Variables on the Proportion of Childhood Spent with No Father for Alternative Specifications

	1	2	3	4	5	6
	Base-line	No state fixed effects	No state or division fixed effects	1 + mother's age 14 family structure	4 + mother's education	5 + mother's AFQT score
Female wage rate

Hispanic	-.061	-.026	-.025	-.040	-.034	-.005

Notes: See the notes to Table 3 for a description of the simulations. The baseline simulations shown in the first column are from the same specification as those reported in the last column of Table 3. However, the simulated values differ slightly from the corresponding entries in Table 3 because the results reported here use the actual parameter estimates rather than 200 draws from the parameter distribution, as in Table 3. All specifications are the same as the baseline except for the difference noted in the column headers.

prob weight	0.303 (0.102)						

Notes: Numfath = Number of the mother's children fathered by the current man. Num cohab = number of previous cohabitations. Prev marr = Married in previous spell (currently single). prev cohab = Cohabited in previous spell (currently single). age youngest = age of youngest child in months/100. age oldest = age of oldest child in months/100. age mother = age of mother in months/100. dur cohab = duration of current cohabitation in months/100. dur single = duration of current single spell in months/100. Factor load = coefficient on the random effect. prob weight = logit of estimated probability weight (log[pw/(1-pw)]). Coefficient estimates on state dummies, division dummies, period dummies, year dummies, and time trends are not shown.

Appendix Table A-3: Comparison of Baseline Simulation Outcomes with Actual Outcomes

	White		Black		Hispanic	
	Actual	Simulated	Actual	Simulated	Actual	Simulated
Mother						
Number of children born	1.71	2.04	1.89	2.42	1.99	2.13
No children	.21	.21	.18	.21	.17	.26
Ever cohabited	.43	.32	.36	.32	.39	.24
Ever married	.89	.87	.62	.74	.82	.78
Marital status at first birth: single	.11	.05	.66	.52	.26	.13
Cohabiting	.03	.03	.04	.04	.06	.04
Married	.85	.92	.29	.45	.68	.83
Age at first birth	25.2	24.1	21.8	21.7	23.3	22.7
Child						
Mother was single at conception	.16	.11	.64	.53	.27	.18
Mother was single at birth	.08	.03	.59	.44	.20	.10
Ever live with no father	.31	.19	.76	.61	.45	.28
Proportion of childhood lived with:						
No father	.12	.07	.55	.33	.22	.12
Married biological father	.77	.87	.33	.48	.65	.79
Cohabiting biological father	.01	.00	.02	.01	.03	.01
Married step father	.06	.05	.07	.16	.07	.07
Cohabiting step father	.02	.01	.03	.02	.03	.01
Ever experience the following event, conditional on being at risk:						
Biological father enters household	.27	.08	.18	.12	.24	.11
Biological father leaves household	.25	.16	.45	.31	.31	.21
Step father enters household	.53	.59	.36	.60	.51	.61
Step father leaves household	.38	.21	.52	.33	.39	.25

Notes: All entries are means. Actual observations are weighted by the inverse of the number of distinct event histories per woman.

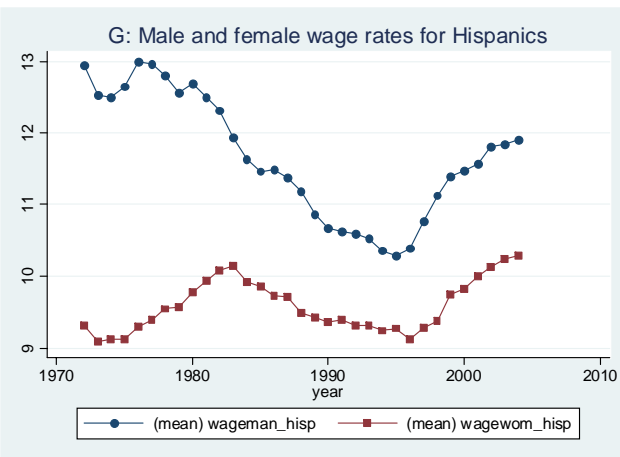

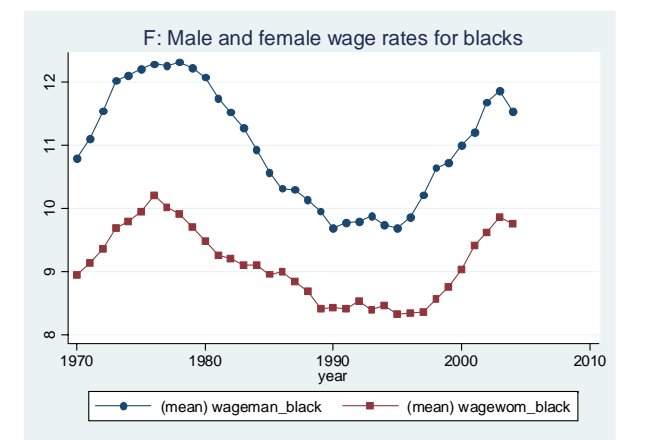

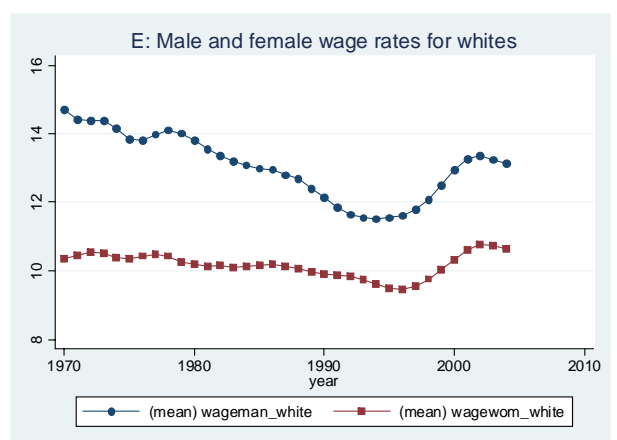

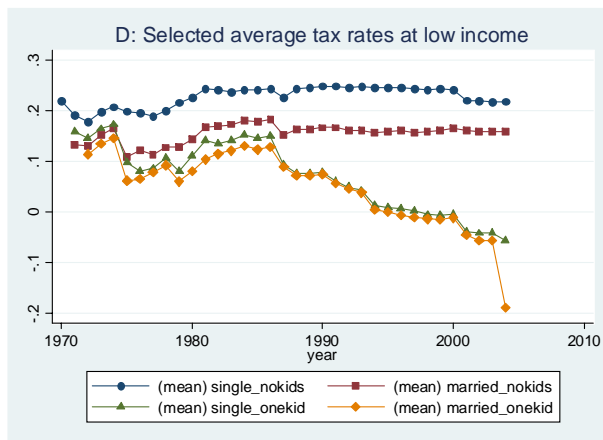

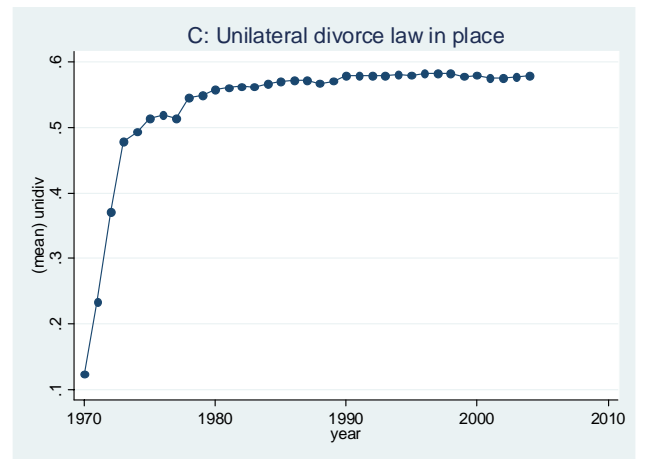

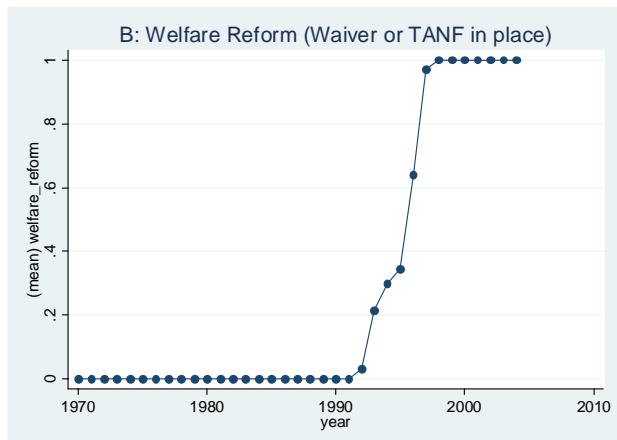

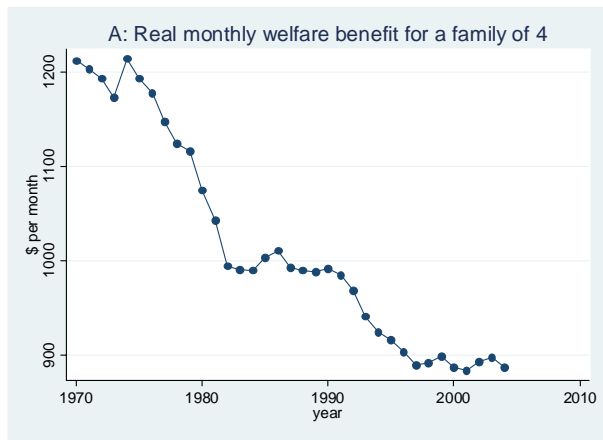

Figure 1: Aggregate Trends in Contextual Variables

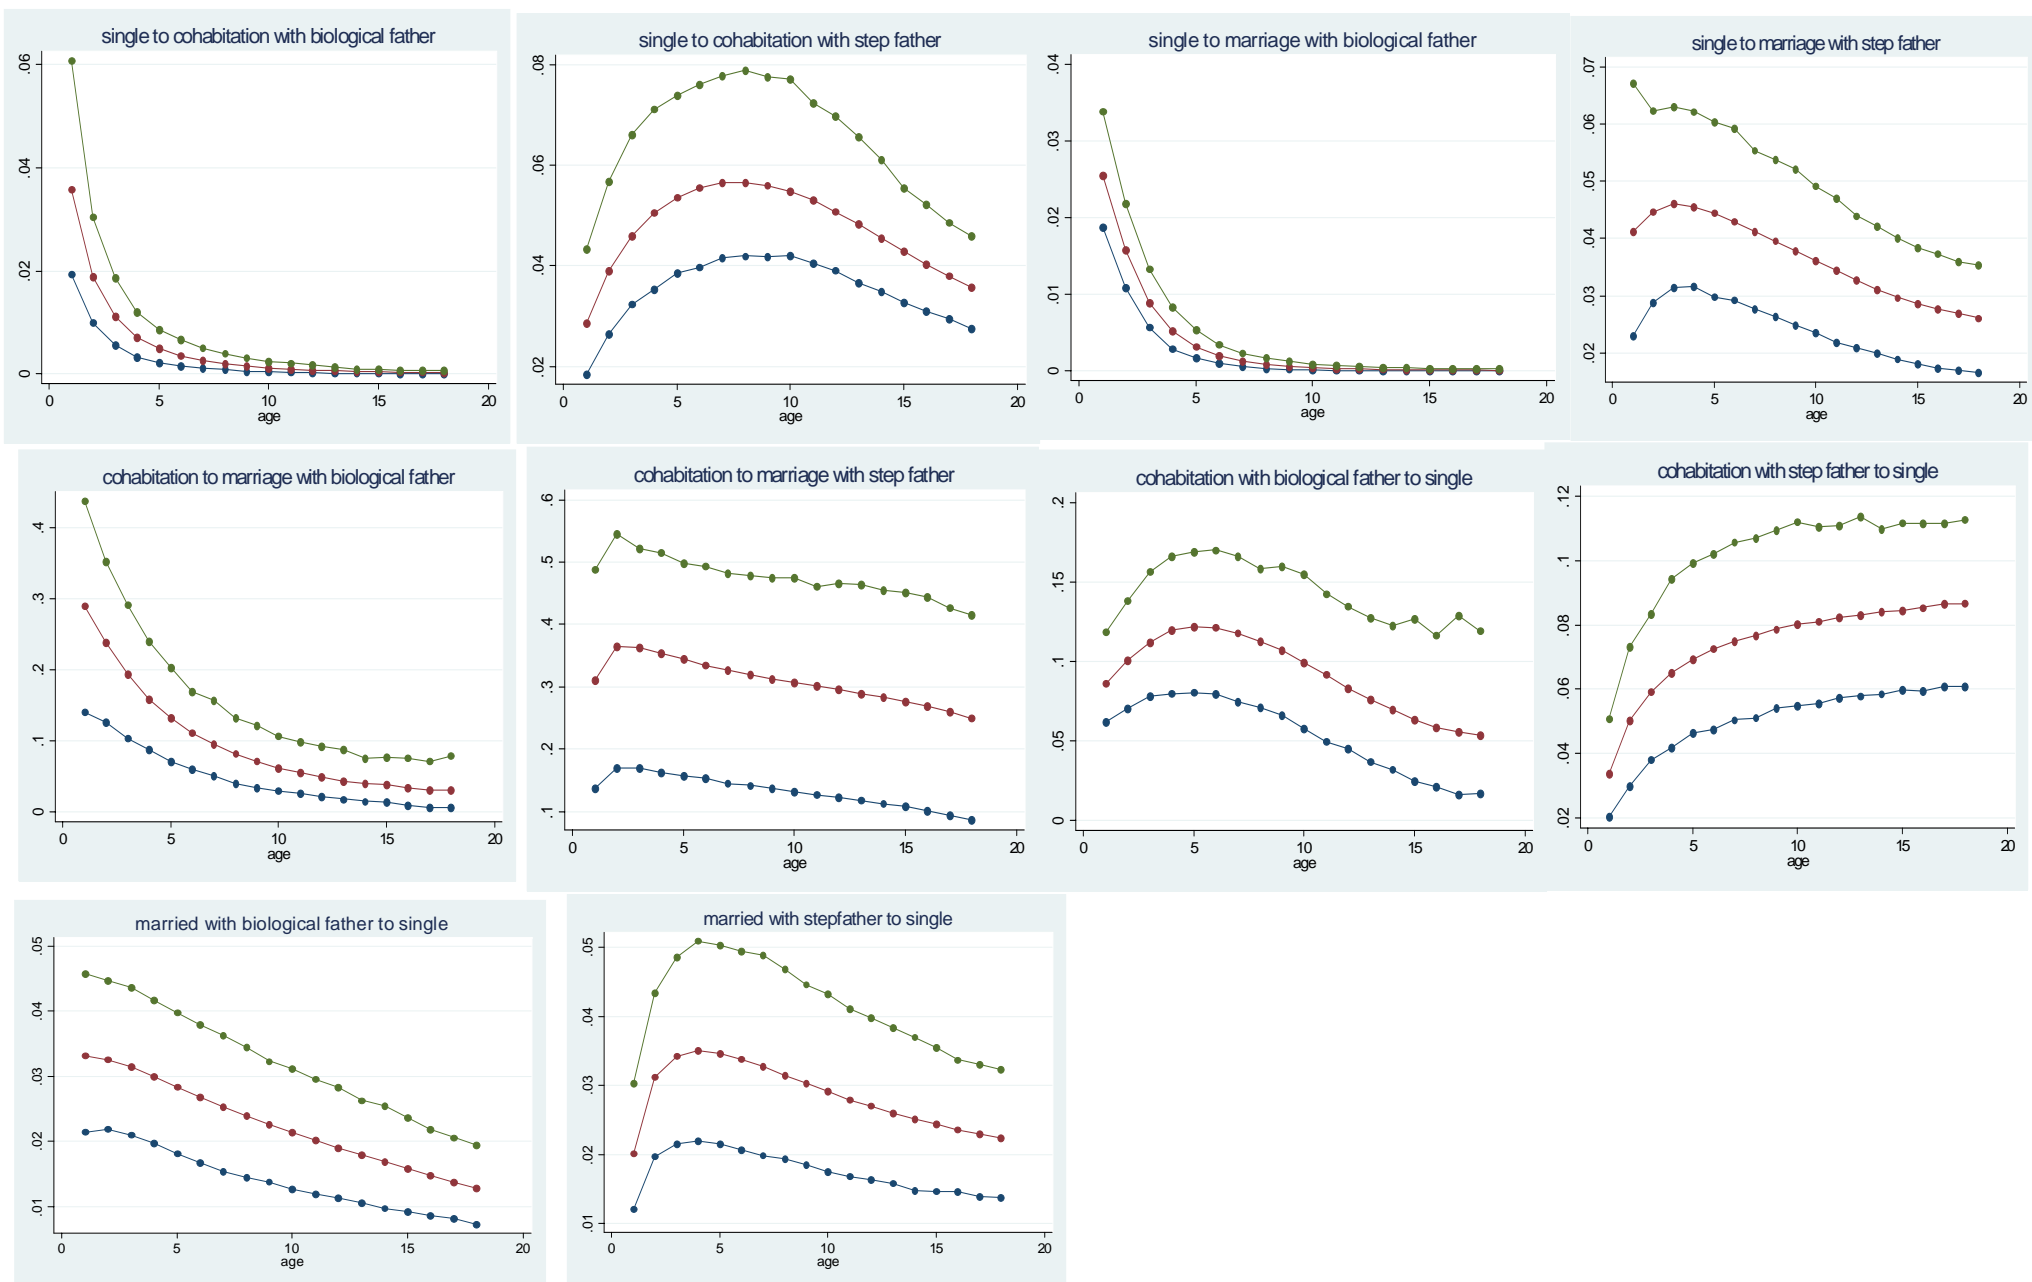

Figure 2: Simulated effect of a one standard deviation increase in the female wage rate on annual family structure transitions of children of black mothers

Notes: The middle line (in red) in each panel is the mean estimate over the 200 draws from the parameter distribution. The other lines are the upper and lower limits of the 95 percent confidence interval.
